Abstract

Combining industry-level data on output and prices with novel monetary policy shock estimates for 102 countries, we analyze how the effects of monetary policy vary with industry characteristics. Next to being interesting in their own right, our findings are informative on the importance of various transmission mechanisms, as they are thought to vary systematically with the included characteristics. Results suggest that monetary policy has greater output effects in industries featuring assets that are more difficult to collateralize or consisting of smaller firms, consistent with the credit channel, followed by industries producing durables, as predicted by the interest rate channel. The credit channel is stronger during bad times as well as in countries with lower levels of financial development, in line with financial accelerator logic. We do not find support for the cost channel of monetary policy, and only limited support for a channel running via exports. Our database (containing monetary policy shock estimates for 176 countries) may be of independent interest to researchers.

I. INTRODUCTION

How does monetary policy affect key macroeconomic variables? Although our understanding of this “transmission mechanism” has improved over time, studies have not reached a consensus regarding the empirical relevance of competing channels (e.g., Mishkin, 1995; Boivin, Kiley, and Mishkin, 2010). This paper aims to enhance our understanding by using a broad panel dataset (featuring 102 countries and 22 industries) covering the period from 1974 to 2019 to analyze the impact of monetary policy on industry-level outcomes. It combines estimates of monetary policy shocks with data on various industry-level characteristics, enabling us to analyze what type of industries (and associated characteristics) are particularly responsive to changes in monetary policy. We argue that the included industry-level characteristics can be related to various monetary transmission channels (though some more precisely than others), generating information on their relative importance.

Economic theory has laid out several channels via which monetary policy can have real effects. Traditionally, the monetary policy literature has distinguished between four different transmission channels (Mishkin, 1995)—the interest rate channel, the exchange rate channel, the asset price channel, and the credit channel; in addition, the literature has also discussed the cost channel (Barth and Ramey, 2001), the signaling channel (Romer and Romer, 2000), as well as the mortgage refinancing channel (Wong, 2019), among many others.

By interacting our estimated monetary policy shocks with industry-level characteristics, we introduce the powerful and influential approach of Rajan and Zingales (1998) to the monetary policy literature. We find evidence that monetary contractions reduce output by more in industries featuring assets that are more difficult to collateralize or consisting of smaller firms, followed by industries producing durable goods. The latter finding supports the interest rate channel, while the former suggests that financial frictions and the associated credit channel of monetary policy are at play. As predicted by the underlying theory, we find that the credit channel is amplified during economic and financial downturns when external financing becomes more difficult to access.

In addition, we do not find consistent evidence for the hypothesis that exporting industries suffer more from a monetary tightening. Instead, our result is more in line with the theory of “dominant currency pricing” (Gopinath et al., 2020): when most traded goods are priced in a “dominant” vehicle currency (typically U.S. dollars), a monetary tightening in the exporting country may well appreciate the associated currency, but does not affect the exchange rate between the importer’s currency and the U.S. dollar—meaning that the standard contractionary impact on exports (as for example present under the assumption of producer currency pricing) does not arise.

Along similar lines, we also test whether the implication of the cost channel of monetary policy, as for example discussed in Barth and Ramey (2001), holds in our industry-level data. The cost channel takes the view that borrowing working capital is a necessary input to the production process (particularly for industries with high liquidity needs), implying that interest rate increases become like adverse cost-push shocks—putting upward pressure on the price level. Our results, however, do not lend support to this view, as the differential effects on price growth are not stronger for industries with higher liquidity needs.

Our paper is most closely related to Dedola and Lippi (2005) and Peersman and Smets (2005), who have also analyzed the heterogeneous impact of monetary policy shocks on different industries, drawing links to the importance of various transmission channels.¹ Relative to these contributions, our paper is much broader in scope—covering 102 countries, including many emerging and developing economies.² Such a broadened coverage supplies the econometric analysis with

¹ Along similar lines, Gertler and Gilchrist (1994) and Carlino and DeFina (1998) study the behavior of small versus large firms in response to monetary policy shocks using U.S. data. They find that small firms tend to be more sensitive to monetary policy, a result consistent with the credit channel (as small firms are typically less able to pledge collateral). Recent work by Corsetti, Duarte, and Mann (2022) explores the drivers of heterogeneity observed within the eurozone in the response to ECB monetary policy shocks; they focus on a set of factors orthogonal to our study, namely the importance of floating rate mortgages, homeownership rates, hand-to-mouth consumers, and wage rigidities—characteristics our Rajan and Zingales (1998)-type approach is not able to test, making our work complementary to theirs.

² The analysis of Dedola and Lippi (2005) is based on five OECD countries, while Peersman and Smets (2005) cover seven eurozone countries. Both studies rely on monetary policy shock identification in a VAR framework employing a recursive identification scheme (following Christiano, Eichenbaum, and Evans, 1999), while we take a different approach (detailed in Section III below). Recently, Auer, Bernardini, and Cecioni (2021) test the credit channel of monetary policy using

greater variation—increasing the signal-to-noise ratio—but is also interesting in its own right as it for example enables us to analyze whether the transmission mechanism meaningfully differs across countries, e.g., based on their level of financial development (which we find to be the case, with the credit channel being more important in countries with less developed financial systems).

In addition, our focus on the *differential* impact of monetary policy on industry-level outcomes (and linking that to industry-level characteristics) eases standard concerns related to reverse causality, which we can address by including a simple-yet-powerful set of fixed effects. We include these on top of the standard strategy of using monetary policy shocks, but since proper identification of the latter remains a formidable challenge (see, e.g., Bauer and Swanson (2023)) we consider the ability to include fixed effects a welcome aid. In particular, our country-industry level panel data setup allows for country-time fixed effects, which absorb any country-specific variation over time and separate the differential impact of monetary policy from unobserved macroeconomic shocks.

In addition to our baseline analysis, we investigate whether the differential effects associated with transmission channels vary with economic conditions. Our findings suggest that the differential effects tend to be more potent during contractions in private credit or output, especially when considering proxies for the credit channel; this is consistent with “financial accelerator” effects stemming from financial frictions, which become more severe in downturns.

The remainder of the paper is organized as follows. In Section II, we discuss the main transmission channels of monetary policy. Section III presents our empirical methodology, after which Section IV describes the data underlying our exercises. Section V presents the main findings and the results of various robustness checks and extensions. Section VI concludes.

seven eurozone countries and 22 manufacturing industries. They use eurozone high-frequency monetary surprises by Jarociński and Karadi (2020) and find that corporate leverage increases the effectiveness of monetary policy.

II. MONETARY TRANSMISSION CHANNELS

As will be set out in greater detail in Section III, this paper looks at the differential impact of monetary policy based on inherent technological characteristics at the industry level that are likely stable across countries and time; see Rajan and Zingales (1998) for a discussion of this assumption. Next to being informative in its own right, an analysis of how the response to changes in monetary policy varies with these characteristics is also informative on the relative importance of the various monetary transmission channels, as they are expected to vary with specific characteristics (even though the relationship is not perfectly clear). As argued by Dedola and Lippi (2005), industry-level data are especially informative on the monetary transmission channel since factors determining the sensitivity to monetary policy typically vary more across industries within a country than across countries.³

As mentioned in the Introduction, the literature has traditionally distinguished four different ways via which changes in monetary policy can affect economic outcomes: the interest rate channel, credit channel, exchange rate channel, and asset price channel (Mishkin, 1995). Since our dataset is not informative on the asset price channel, we focus on the remaining three. The availability of an additional dataset (featuring industry-level price deflators) also enables us to investigate the cost channel. The latter features in several prominent models (such as Christiano, Eichenbaum, and Evans (2005)) and has important implications for the optimal conduct of monetary policy (Ravenna and Walsh, 2006).

1. The interest rate channel. This channel is typically seen as the main “Keynesian” transmission mechanism, whereby a monetary contraction (increase in the short-term interest rate) ends up pushing up longer-term rates through the expectations-hypothesis of the term structure. With prices being sticky, this translates into an increase in the real interest rate. Firms (consumers) respond to

³ Recently, several studies have analyzed the monetary transmission mechanism using firm-level data (see, e.g., Jeenas, 2019; Ottonello and Winberry, 2020; Durante, Ferrando, and Vermeulen, 2022; Cloyne et al., forthcoming). However, the use of firm-level data has its shortcomings as these data typically have much narrower coverage for developing economies. In that sense, we see our industry-level analysis as complementary to recent firm-level studies.

this increased cost of capital by cutting back on investment (durable purchases), which depresses output and prices. However, since our dependent variable is output (not investment), our findings cannot identify the impact of the interest rate channel on firms' investment directly (we can only see any effect this may end up having on value-added growth in each industry).

2. *The credit channel.* This channel is associated with the seminal contributions of Bernanke and Gertler (1989) and Bernanke, Gertler, and Gilchrist (1999), who developed the idea that a monetary contraction reduces firms' net worth (the sum of liquid assets and marketable collateral, less outstanding obligations).⁴ This makes borrowers less able to put up collateral for their loans, increasing agency problems: firm owners now have less "skin in the game," making them more likely to engage in risky investment strategies that are not in lenders' interest. To compensate for this risk, lenders will charge a higher interest rate (via the "external financing premium"), reducing firm investment and thus output. However, due to the inherent difficulty in observing the external financing premium, the literature has relied on various proxies for financial constraints (firm size, age, leverage, dividend payout, etc.) when testing this channel.

In particular, firms that face greater inherent difficulties in pledging collateral (e.g., due to their smaller size or the nature of their assets) are believed to be more vulnerable to this mechanism (Gertler and Gilchrist, 1994), with downturns making creditors "flee to quality" (credit flowing away from borrowers without much collateral; Bernanke, Gertler, and Gilchrist, 1996). In line with this narrative, unsecured debt is found to be strongly procyclical in U.S. data (Azariadis, Kaas, and Wen, 2016), with the unsecured credit spread going up in recessions (Benmelech, Kumar, and Rajan,

⁴ Occasionally, the credit channel is separated into the balance sheet channel (focusing on the borrower's side) and the bank lending channel (focusing on the lender's side, with a change in monetary policy affecting borrowing rates and volumes, which then impacts output and prices). Since we have no access to data on bank lending, we cannot separately identify these two channels. As Braun and Larrain (2005: 1102) note: "In practice, the distinction between the balance sheet and the bank lending view becomes blurred when the correlation between dependence on external funds and dependence on bank loans is high, or when banks are the predominant source of external finance." Since many emerging/developing economies in our sample do not have well-developed corporate bond markets like the United States, focusing on the broad credit channel appears a reasonable approach.

2022).⁵ As a result, firms with fewer collateralizable assets are expected to be more sensitive to monetary contractions (and economic slowdowns in general); in this context, Bernanke, Gertler, and Gilchrist (1999, pp. 1374-5) also speak of “excess sensitivity” to monetary shocks for firms that are more financially constrained.

3. The exchange rate channel. Since monetary contractions typically appreciate the home currency, they can reduce net exports and aggregate demand (Taylor, 1995). The exact mechanism however varies depending on the currency in which prices are set. In particular, when prices are set in the producer’s (i.e., exporter’s) currency, a depreciation of the exporter’s currency will make the exporter’s good cheaper for importers elsewhere, predicting that a monetary tightening (typically leading to exchange rate appreciation) should contract output by more in more export-dependent industries. In practice, however, prices for many traded goods are set in U.S. dollars (even if both exporter and importer reside in countries where the U.S. dollar is not legal tender; Gopinath et al., 2020). An appreciation of the home currency then has no direct impact on external demand for home exports, as the exchange rate between importer currencies and the U.S. dollar is not affected; net exports may still fall, but in this case mainly through higher imports.

4. The cost channel. The last theoretical channel we investigate is the cost channel of monetary policy, as, e.g., emphasized by Barth and Ramey (2001); it also features in the influential model by Christiano, Eichenbaum, and Evans (2005). When firms need to pay factors of production (wages, inventories, etc.) before receiving sale revenues, they must “bridge” the resulting gap by borrowing some working capital. Effectively, this turns the cost of borrowing into an input to the production process, meaning that interest rate increases become like adverse cost-push shocks. Thus, a distinctive prediction of the cost channel is that a contractionary monetary shock will increase prices for products produced by firms that rely more heavily on external financing. Needless to say, such a flipped response of prices to monetary shocks has important implications for the optimal conduct

⁵ As noted in Azariadis, Kaas, and Wen (2016), these observations call for models featuring both secured and unsecured financing (to capture the “flight to quality” out of unsecured lending during downturns), such as Azariadis, Kaas, and Wen (2016) and Luk and Zheng (2022).

of monetary policy (Ravenna and Walsh, 2006), making it important to analyze whether this channel has empirical relevance.

In the remainder of this paper, we aim to shed some light on the importance of these channels by analyzing the industry-specific responses to monetary policy shocks. Since the above channels are likely to differ in their importance across industries (depending on industry-specific characteristics, more on which in Section IV.A), this “differential” approach (laid out in Section III) can teach us something about *how* changes in monetary policy end up affecting output and prices.

III. METHODOLOGY

As stated in the Introduction, the focus of this paper is different from the majority of papers in the monetary policy literature. While most papers—those in the tradition of Christiano, Eichenbaum, and Evans (1999)—aim to identify the causal effect of surprise changes in monetary policy on macroeconomic variables of interest (such as output, inflation, and exchange rates), we have a different objective: we wish to analyze what industry-level characteristics are affecting the responsiveness of economic activity to monetary policy shocks.

Given this different objective, we can (and will) deploy a different method. Next to the fact that a diversity of approaches is generally desirable to assess the robustness of earlier findings, our method has the added benefit (relative to VAR-based studies, such as Peersman and Smets (2005) and Dedola and Lippi (2005)) that it is less dependent on the direct identification of structural shocks. In most studies analyzing the effects of monetary policy, shock identification is as crucial as it is difficult and controversial (Ramey, 2016).

Instead, our focus on differential outcomes at the industry level enables us to further mitigate endogeneity concerns by including multi-way fixed effects (on top of taking more standard approaches to monetary policy shock identification). This fixed-effects approach has been deployed to overcome endogeneity issues in a wide variety of different contexts, including when analyzing the channel through which growth is affected by financial development (the seminal paper by Rajan and Zingales (1998)), by the occurrence of recessions (Braun and Larrain, 2005; Samaniego and Sun,

2015), by banking crises (Kroszner, Laeven, and Klingebiel, 2007; Dell’Ariccia, Detragiache, and Rajan, 2008), and many other factors. However, to the best of our knowledge, ours is the first study to use this “Rajan-Zingales approach” to analyze the differential impact of monetary policy on different industries using a large international panel dataset.

A. Econometric specification

To analyze the importance of industry-level characteristics in the monetary policy transmission process, we apply the methodology in Braun and Larrain (2005) and Dell’Ariccia, Detragiache, and Rajan (2008), which extends the two-way fixed effect setup (country-industry) in Rajan and Zingales (1998) to a three-dimensional panel setup (country-industry-time). See Angrist and Pischke (2009) for how a multi-way fixed effect approach can be seen as a generalization of the difference-in-differences approach to draw a causal inference, while Gormley and Matsa (2014) offer a more formal econometric discussion with related examples. Specifically, we estimate the following specification for an unbalanced panel of 102 countries and 22 manufacturing industries over the period 1974-2019:

$$Y_{i,c,t+1} = \alpha_{i,c} + \alpha_{i,t} + \alpha_{c,t} + \beta(X_i \times MPS_{c,t}) + \gamma Share_{i,c,t} + \varepsilon_{i,c,t+1}, \quad (1)$$

where i denotes industries, c countries, and t years. $Y_{i,c,t+1}$ is a measure of industry growth during year $(t+1)$.

The variable X_i characterizes industry i along a certain dimension (seven in total, such as external financial dependence, asset tangibility, and durability of output; see Section IV.A for details); $MPS_{c,t}$ is our proxy for the monetary policy shock for each country c during year t (with positive values indicating monetary contractions; see Section III.B for details); finally, $Share_{i,c,t}$ is the share of industry i in country c ’s total manufacturing sector value-added at time t (included to allow for “convergence effects”, i.e., the possibility that larger industries tend to grow more slowly). When testing the cost channel of monetary policy, we replace output growth with the growth of price deflators $\pi_{i,c,t}$ at the country-industry level:

$$\pi_{i,c,t+1} = \alpha_{i,c} + \alpha_{i,t} + \alpha_{c,t} + \beta(X_i \times MPS_{c,t}) + \gamma \pi_{i,c,t} + \varepsilon_{i,c,t+1}. \quad (1')$$

Note how regression (1) also contains industry-country, industry-time, and country-time fixed effects ($\alpha_{i,c}$, $\alpha_{i,t}$, and $\alpha_{c,t}$, respectively). This constitutes a powerful set of controls, reducing lingering concerns about omitted variables, model misspecification, or reverse causality (Rajan and Zingales, 1998; Braun and Larrain, 2005; Dell’Ariccia, Detragiache, and Rajan, 2008). After all:

- industry-country fixed effects ($\alpha_{i,c}$) control for all industry i -country c -specific factors that affect the growth of industry i in country c (such as a country’s industrial policies, to the extent that they persist over time);
- industry-time fixed effects ($\alpha_{i,t}$) control for all global factors impacting the growth rate of industry i at year t across all countries in the sample (e.g., a positive oil price shock, which is expansionary for the oil-producing sector but contractionary for the transport sector);
- country-time fixed effects ($\alpha_{c,t}$) control for all macroeconomic developments affecting country c in year t (such as the state of the country’s business cycle), including any aggregate effects stemming from monetary, fiscal, or other policies.

Given the presence of these fixed effects, the only remaining source of variation is quite narrow—namely factors that are specific to industry i in country c during year t , such as our interaction term of interest ($X_i \times MPS_{c,t}$). The main object of interest in equation (1) is β , the coefficient on the interaction term ($X_i \times MPS_{c,t}$). The interpretation of β is akin to a difference in differences (Angrist and Pischke, 2009), which measures the *differential* impact of monetary contractions in industries with characteristics as proxied by X_i .

This coefficient is informative about what type of industries are particularly affected by the monetary policy shock, which is, in turn, informative about the relevance of the various transmission channels. By differentiating equation (1) one obtains that $\beta = \partial^2 Y_{i,c,t+1} / \partial X_i \partial MPS_{c,t}$. When $\beta < 0$, this means that a monetary contraction ($MPS > 0$) ends up having a larger negative effect on output growth in industries that score higher along characteristic X . Following Abadie et al. (2023), we cluster standard errors at the treatment level, which is country-by-time (but alternative clustering, such as country-by-industry, hardly affects the main conclusion).

B. Endogeneity and our measure of monetary policy shocks

In studies analyzing the effects of monetary policy, the main challenge is typically to overcome the fact that monetary policy is highly endogenous (Ramey, 2016). Following a change in the stance of monetary policy, one does not know whether any observed impact is the cause or the effect of that policy change.

On this front, the approach developed by Rajan and Zingales (1998) is a welcome aid. As discussed in Section III.A, this specification allows for a powerful set of controls—most notably country-time fixed effects ($\alpha_{c,t}$). Their presence implies that we can “freeze” the aggregate state of the economy during year t (rate of growth, inflation, etc.), only analyzing a “partial” change in monetary policy—one that delivers a stronger “treatment” to agents operating in an environment characterized by higher X (and no treatment to agents operating under $X = 0$). Suppose it is true that the inherent characteristic measured by X makes an industry more sensitive to monetary policy shocks. Then, we should find that the resulting estimate for β is significantly different from zero (in particular, smaller than zero if “high- X ” industries are more prone to contract following a monetary tightening).

Our focus on the differential impact based on industry-level characteristics alleviates concerns about reverse causality—especially in combination with the inclusion of country-time (and other) fixed effects. In this setup, claiming reverse causality is equivalent to arguing that monetary policy is set with an eye toward differences in growth rates across industries. This strikes us as implausible. In addition, our independent variable of interest is an interaction term consisting of the product of our estimates of monetary policy shocks and industry-specific characteristics obtained from U.S. firm-level data (see Section IV.A)—making it even more unlikely that causality runs from industry-level growth to this interaction variable.

But next to worries about reverse causality, there is also the possibility that endogeneity stems from an omitted variable bias. After all, country c ’s central bank is likely to determine its monetary policy stance by looking at developments in certain macro-variables, which may in and of themselves bring about differential responses in the various industries included in our analysis. For

example, a central bank may tighten monetary policy in response to inflationary pressures, growth exceeding potential, or exchange rate depreciation. If those drivers of monetary policy decisions have a heterogeneous impact on different industries based on their underlying characteristics X_i (e.g., exchange rate depreciation benefiting exporting industries), $\hat{\beta}$ would not give an unbiased estimate of the differential impact of pure changes in monetary policy; instead, the impact of the underlying drivers of the change in monetary policy (depreciation of the exchange rate, in this example) would shine through.

To address this concern, we do our best to identify proper monetary policy *shocks* for all country-year pairs in our sample. Note that this is a deviation from (we would argue: an improvement over) the traditional Rajan-Zingales approach, which does not attempt to purge the interaction term from any endogeneity—fully relying on the constellation of fixed effects instead. More specifically, we take a hierarchical approach when it comes to shock identification that can be summarized as follows:

- i. Where available, we take monetary policy surprises as identified by *high-frequency studies* in the spirit of Kuttner (2001), which is widely used in the recent literature to estimate the causal effects of monetary policy. In particular, we take surprises from Bauer and Swanson (2023) for the U.S. (1988-2019), Jarociński and Karadi (2020) for the eurozone (1999-2016), Cesa-Bianchi, Thwaites, and Vicendoa (2020) for the U.K. (1997-2015), Champagne and Sekkel (2018) for Canada (1974-2015), Holm, Paul, and Tischbirek (2021) for Norway (1990-2018), Amberg et al. (2022) for Sweden (1999-2018), Alberola et al. (2021) for Brazil (2001-2017), Lakdawala and Sengupta (forthcoming) for India (2003-2020), Kubota and Shintani (2022) for Japan (1992-2020), and Ahn, Kim, and Lee (2021) for Korea (2009-2018). We follow the convention that a positive surprise corresponds to a monetary contraction.
- ii. If i) is not available, we proxy the monetary policy shock by the *one-day change in the 3-month swap yield* (obtained from Bloomberg) around monetary policy decision days, i.e., the yield at the close of day T minus the yield at the close of day (T-1), with the

decision taking place sometime on day T .⁶ The floating leg of interest rate swaps is tightly linked to the stance of monetary policy and any changes around monetary policy decision dates should proxy the monetary surprise. This approach goes back to the pioneering work of Skinner and Zettelmeyer (1996).

- iii. If i) and ii) are not available, we proxy the monetary policy shock by the *one-day change in the short-term domestic government bond yield* around monetary policy decision days. We look at the shortest possible tenor, only considering bonds with an original maturity of less than a year (i.e., domestic t-bills of 1, 3, 6, or 12-month maturity) as obtained from Bloomberg. Those are typically excluded from debt restructuring operations (which, more generally, tend to focus on *external* debt only), meaning that they do not carry a default risk premium—being intimately linked to the monetary policy stance instead. Focusing on a narrow one-day window around any policy rate decisions further helps to eliminate (difference out) a default premium, if somehow present.
- iv. If i), ii), and iii) are not available, we rely on *Bloomberg’s survey of financial market participants* to obtain prior (i.e., pre-decision) expectations for each monetary policy rate decision and proxy the shock by subtracting this prior expectation from the subsequent realization (so that positive values, again, correspond to contractionary surprises).
- v. When i), ii), iii), and iv) are not available (the case for most lower-income countries), we proxy the monetary policy shock by taking *residuals from an estimated Taylor rule*. While this approach may be too crude for advanced economies characterized by a wealth of financial market data, it may be a reasonable way forward for developing countries where data are scarce and forecasts are even scarcer. This naturally puts growth and inflation data (two series commonly available for all countries) at the center of attention,

⁶ Dates of monetary policy decisions are obtained from Bloomberg. Ideally, one would wish to use a narrower window around the announcement of the rate decision (of, say, 24 *minutes* rather than 24 *hours*) but the exact hour:minute-information of monetary policy announcements is typically not available for emerging market and developing economies. Moreover, as their financial markets tend to be less liquid than those of the U.S. and other advanced economies, there is a good reason to allow more time for the news to be incorporated.

implying that policy-rate forecasts may be well-approximated by a Taylor rule.⁷ We obtain Taylor residuals by estimating equation (2) country-by-country via OLS, following the suggestion by Carvalho, Nechio, and Tristão (2021).

The specific rule we estimate postulates that the systematic component of monetary policy is set with an eye toward a country’s real GDP growth, inflation, and exchange rate (given its likely impact on future inflation). In particular, for each country c we estimate:

$$\Delta R_t = \theta + \sum_{j=1}^3 \kappa_j g_{t-j} + \sum_{j=1}^3 \lambda_j \pi_{t-j} + \sum_{j=1}^3 \tau_j \Delta e_{t-j} + \sum_{j=1}^3 \rho_j \Delta R_{t-j} + \varepsilon_t^R, \quad (2)$$

where ΔR_t is the change in the central bank’s policy rate, g_t is the real rate of economic growth, π_t is the rate of inflation, and Δe_t is the change in the logged nominal exchange rate vis-à-vis the U.S. dollar (all during year t); note that (2) also includes lags of the dependent variable, to allow for interest rate smoothing.⁸ We include three lags of all variables in (2) since past developments may affect monetary policy decisions during year t .⁹ Importantly, results are robust to a variety of alternative specifications—both

⁷ In fact, even for the U.S., we obtain a significant positive correlation (of 0.43) between the annualized shocks identified through high-frequency methods by Bauer and Swanson (2023) and the U.S.’s Taylor residuals that follow from equation (2). We view this as encouraging regarding the potential for our Taylor residuals to approximate the true monetary policy shocks in less-developed economies. Barnichon and Brownless (2019) also show encouraging results (their Figure 3) when it comes to using residuals from a Taylor rule to proxy U.S. monetary policy shocks.

⁸ Data on GDP growth and the exchange rate are taken from the IMF’s WEO database; the inflation data come from the World Bank’s Global Inflation Database constructed by Ha, Kose, and Ohnsorge (2021) which constitutes a comprehensive, single source for inflation series with greater coverage than other publicly available databases; data on monetary policy rates are taken from Haver and, where complementary, the IMF’s IFS database. The rates are quoted annually at end-of-period values, enabling us to calculate the change in the policy rate during each year ($\Delta R_{c,t}$). After conditioning on countries with at least ten years of available data, coverage is such that we have policy rates for 84 countries, with an average time dimension (at the country level) of 29 years.

⁹ Our Taylor rule specification (2) does not include any *forecasts* for growth and inflation, but those tend to be less important in emerging/developing economies where such variables are more difficult to predict (and forecasting capacity might be lower); recently, even the U.S. Federal Reserve has signaled that it will attach a lower weight to forecasted inflation (Clarida, 2021). In addition, as for example argued by Stock and Watson (2003), forecasts for both growth and inflation are typically well described by an autoregressive representation, which does feature in equation (2)—as does the nominal exchange rate, which tends to be another strong determinant of future inflation (especially for open economies with strong exchange rate pass-through).

when it comes to different lag structures as well as to dropping Δe_t or adding additional variables (like the change in oil prices).

- vi. If i), ii), iii), iv), and v) are not available, and the country under consideration pegged its exchange rate to some anchor currency in a given year (per Ilzetzki, Reinhart, and Rogoff (2019)), we use the *estimated monetary policy shock in the anchor country*. This follows the standard trilemma logic, implying that pegging countries end up importing monetary policy from the anchor country (subject to capital account openness). This strategy also underlies Willems (2013) and Jordà, Schularick, and Taylor (2020). Following the latter paper, we proxy the monetary policy shock for the receiving country by multiplying the original shock in the anchor country with the Chinn-Ito measure of capital account openness (Chinn and Ito, 2006), which runs continuously between 0 (when the capital account is fully closed) and 1 (indicating a fully open capital account). This adjusts the strength of the instrument in line with the degree of capital account openness, as the trilemma dictates (Jordà, Schularick, and Taylor 2020: 25).

Proxies i), ii), iii), and iv) are calculated on days of monetary policy announcements so we annualize them by cumulation (since our dependent variable is only available at the annual frequency).

Table 1. Sourcing of our monetary policy shock proxies

Source	Share (I)	Share (II)
High-frequency studies	9.0%	59.5%
Change in swap yields	3.9%	3.9%
Change in bond yields	0.9%	0.9%
Survey-based measure	2.1%	2.1%
Taylor residuals	23.7%	33.5%
Taken from anchor countries	60.3%	n/a
<i>High-frequency studies</i>	<i>50.5%</i>	
<i>Change in swap yields</i>	<i>0.0%</i>	
<i>Change in bond yields</i>	<i>0.0%</i>	
<i>Survey-based measure</i>	<i>0.0%</i>	
<i>Taylor residuals</i>	<i>9.8%</i>	

Table 1 shows the sourcing of the monetary policy shock proxies when constructing the series in the above way. Given the prevalence of pegging (as documented by Ilzetzki, Reinhart, and Rogoff (2019)) over half of the monetary policy shocks are taken from anchor countries (see Column (I)); since those are all advanced economies, most shock estimates for anchor countries are obtained through high-frequency methods. When allocating the shock proxies taken from anchor countries to the original sources (as done in Column (II) of Table 1), we see that only a third of all shocks are estimated Taylor residuals; the other two-thirds are obtained through more sophisticated methods, with shock estimates taken from pre-existing high-frequency studies accounting for almost 60% of all 5,433 observations. Figure A.1 in the online appendix provides a visual summary of sources of monetary policy shock estimates for every country (row) and year (column) pair used in our analysis.

Figure 1. Impulse-responses following a positive monetary policy shock

Note: The figure shows responses to a one percentage point contractionary monetary policy shock. Shaded areas represent the 90% confidence interval.

Reassuringly, using the resulting monetary policy shock series in a panel Local Projections (LP) framework yields puzzle-free responses for the cyclical components of real GDP and the GDP deflator (Figure 1), giving credence to the underlying shock series that sits at the core of the remainder of this paper. The cyclical components of real GDP and the GDP deflator are obtained by applying the Hamilton (2018) filter at the country level, while the LPs include a standard set of

controls: country fixed effects, three lags of the cyclical component of real GDP, three lags of the cyclical component of the GDP deflator, and three lags of the short-term interest rate.¹⁰

Since there is no denying that identifying true monetary policy shocks is difficult (even in circumstances where the high-frequency route is open; see Bauer and Swanson (2023)), we re-emphasize that we not only deploy our best efforts on this front (as described by points i)-vi) above), but also include industry-country ($\alpha_{i,c}$), industry-time ($\alpha_{i,t}$), and country-time ($\alpha_{c,t}$) fixed effects in equation (1)—further controlling for a broad range of factors, mitigating concerns related to reverse causality via that approach (recall the discussion in Section III.A).

IV. DATA

A. Technological characteristics at the industry level

Since our ultimate objective is to investigate whether certain technological characteristics make specific industries respond differentially to changes in monetary policy, we need to obtain industry-level data on those characteristics. This places our paper in the Rajan-Zingales tradition. At the core of Rajan and Zingales (1998) lies the assumption that technological factors vary systematically across industries—a notion for which we will present supporting evidence in Section V.B (which will also show that our main result, the relevance of the credit channel, is robust to using a *country-specific* variable proxying access to credit for each industry).

In line with earlier studies, such as Dedola and Lippi (2005) and the large literature following Rajan and Zingales (1998), most of our industry characteristics are measured using U.S. firm-level or industry-level data. These are assumed to represent technological characteristics in a relatively frictionless and unregulated environment, serving as our analysis’ natural benchmark. Basing industry characteristics on U.S. data has an additional advantage of mitigating concerns regarding reverse causality (recall Section III; industry i developments in country c are unlikely to affect the

¹⁰ Although qualitative responses remain the same, the timing of the aggregate output effect is somewhat sensitive to the exact cyclical indicator included: when using the rate of growth (instead of the cyclical component following from the Hamilton filter), the effect peaks in year 1.

U.S. metrics that determine X_i). To the extent that certain industries are fundamentally and persistently different in other countries, this will be picked up by the industry-country fixed effects ($\alpha_{i,c}$).

To generate insights into the nature of monetary policy transmission, we use the following seven industry-level characteristics (which have been linked to the various transmission channels before, as discussed below). Unless mentioned otherwise, these measures are taken from Samaniego and Sun (2015), who construct industry characteristics at the three-digit ISIC level using U.S. firm-level data. We aggregate them up the two-digit ISIC level employed in our analysis using the industry-level average value-added during the sample period as a weight, as in Choi, Furceri, and Jalles (2022).¹¹

1. *External financial dependence (EFD)*. Following Rajan and Zingales (1998), dependence on external finance in each industry is proxied by that share of capital expenditure that is not financed by cash flow from operations; the industry value is that of the median U.S. firm in each industry. External financial dependence captures firms' need for external financing and is employed by, *inter alia*, Dedola and Lippi (2005) to test the credit channel of monetary policy. According to the latter, we expect a negative sign on the interaction term between external financial dependence and the monetary policy shock (as firms relying more heavily on external funding are more vulnerable to an increase in the premium driven by a monetary tightening). At the same time, according to the cost channel of monetary policy, firms with heavy reliance on external funding are more likely to raise the prices of their products following a monetary contraction, predicting a positive interaction term when the dependent variable is the price deflator.

2. *Asset tangibility (TAN)*. Asset tangibility measures the share of tangible capital in a firm's total assets and hence proxies the fraction of a firm's assets that can be pledged as collateral to obtain funding (Hart and Moore, 1994). Asset tangibility can therefore be seen as a measure of an industry's

¹¹ The UNIDO INDSTAT3 dataset used in Samaniego and Sun (2015) was discontinued. Currently, only the INDSTAT2 and INDSTAT4 databases are provided by UNIDO.

access to secured credit and its industry-level values are used in the Rajan-Zingales-based literature to proxy for the importance of the credit channel (Braun and Larrain, 2005; Aghion, Hemous, and Kharroubi, 2014).

The logic is that firms with plenty of tangible (collateralizable) assets will find it easier to obtain external funding after a monetary tightening compared to firms without tangible assets since secured credit tends to be more stable over the cycle (Azariadis, Kaas, and Wen, 2016; Benmelech, Kumar, and Rajan, 2022). Indeed, this kind of exercise was explicitly performed by Bernanke, Gertler, and Gilchrist (1999: 1374-5) to demonstrate how firms without access to secured credit show excessive sensitivity to monetary policy shocks. As a result, industries high on asset tangibility can be expected to suffer less following a contraction, implying that the interaction term between asset tangibility and ΔMP should be positive if the credit channel is important.

3. *Average firm size (SIZE)*. Firm size is thought to be a good proxy for especially the ability to draw external funds, with bigger firms enjoying greater access to external financing—for example, on the back of better access to capital markets, greater availability of assets that can be collateralized, or creditors facing smaller informational disadvantages (see, e.g., Gertler and Gilchrist, 1994; Beck et al., 2008; Hadlock and Pierce, 2010). Indeed, Beck et al. (2008) show that their firm size measure is correlated with asset tangibility but not with external financial dependence in U.S. data, which we also confirmed in our data (Table 3).

An important advantage of using firm size as a measure of financial constraints is that this measure can be constructed at the country level (not just for the U.S.) to validate the crucial assumption in our difference-indifferences approach.¹² We compute the average firm size (in terms of the number of employees) of each industry by dividing the number of employees by the number

¹² Although this assumption is standard in the literature following Rajan and Zingales (1998) and also received some empirical support in studies using cross-country data on technological factors (Carlin and Mayer, 2003; Kroszner, Laeven, and Klingebiel, 2007; Ilyina and Samaniego, 2011), it is still important to check that this assumption is not driving our main result regarding the importance of each channel. We conduct a robustness check using both U.S. firm size and country-specific firm size measures.

of establishments taken from UNIDO, and then average over the sample period.¹³ We then take a median value across countries in the sample to further mitigate measurement errors. The correlation between the resulting industry-level firm size measure and the U.S. measure is 0.57, suggesting the stability of this measure across countries.

4. *Liquidity needs (LIQ)*. Liquidity needs are taken from Raddatz (2006) and are measured by the ratio of inventories to sales, which proxy for the reliance on short-term working capital to maintain inventories. Note that liquidity needs capture somewhat different dimensions of credit constraints relative to the aforementioned technological characteristics, as they are not associated with collateral pledgeability and are likely a short-run phenomenon (Aghion et al., 2009; Lee, 2023). Thus, investigating this channel also helps sort out the relative importance between the “ability to secure” and “need to obtain” external funds. Simultaneously, when using prices as a dependent variable, consideration of LIQ is informative on the relevance of the cost channel, which is about short-term borrowing requirements.

5. *Capital depreciation (DEP)*. This variable is computed using industry-specific rates of depreciation from the BEA’s capital flow tables. It is based on the resale value of capital goods and thus reflects all factors that result in the decline in the value of capital goods, including both physical and economic depreciation. Similar to asset tangibility, capital depreciation can be used to test the credit channel of monetary policy because less durable capital stocks are not readily collateralizable (suggesting a weaker ability to secure external financing, see for example, Carrillo and Poilly (2013) and Beutler and Grobéty (2019)).

6. *Durability (DUR)*. Following Dedola and Lippi (2005) and Peersman and Smets (2005), we use a binary dummy for durability, which takes a value of one if the industry produces durable goods. Durability is defined by the economic destination of production from the national accounts statistics, and 12 out of 22 industries fall into this category. The durability of goods produced by each industry

¹³ While we take the average over time to reduce potential measurement errors, the ranking of industries according to their size is highly stable over time. Using value-added (instead of the number of employees) as a size proxy yields similar results.

is useful in testing the conventional interest channel of monetary policy. This channel predicts a stronger effect of monetary policy on industries producing more durable goods, as such purchases are often financed by credit and thus more sensitive to interest rates.

7. *Export intensity (EXP)*. Data on this characteristic are taken from Giovanni and Levchenko (2009), who calculated industry-level averages of the ratio of industry-level exports to value-added. Similar to Dedola and Lippi (2000) and Peersman and Smets (2005), we use this variable to test the exchange rate channel of monetary policy. To the extent that a domestic monetary tightening leads to an appreciation, industries more reliant on exports may suffer more. Note that this characteristic is only testing the export-related part of the exchange rate channel: it is important to keep in mind that the latter also allows for an effect on imports, but since our dataset only spans the value-added growth of different industries, we are not able to analyze the impact on, e.g., imports of final consumer goods.

In Table 2 we summarize how each industry characteristic relates to the theoretical transmission channels discussed in Section II, adding the predicted sign of the interaction term according to the underlying channel.

Table 2. Industry-level characteristics and associated theoretical channels

Characteristics	Corresponding transmission channels	Expected sign on the interaction term (β)
EFD	Credit channel (needs)	–
	Cost channel (if $Y_{i,c,t}$ is price growth)	+
TAN	Credit channel (ability)	+
SIZE	Credit channel (ability)	+
LIQ	Credit channel (needs)	–
	Cost channel (if $Y_{i,c,t}$ is price growth)	+
DEP	Credit channel (ability)	–
DUR	Interest rate channel	–
EXP	Exchange rate channel	–

Note: EFD (external financial dependence), TAN (asset tangibility), SIZE (average firm size), LIQ (liquidity needs), DEP (capital depreciation), DUR (durability), EXP (export intensity). “Ability” refers to the ability to secure external financing; “needs” refers to the need for external financing.

Table 3 presents the correlation matrix of these variables, which does not point to correlations that are exceedingly high. To ease the comparison of the economic magnitude across

different transmission channels, we normalize each measure X to have a zero mean and unit standard deviation over all industries.

Table 3. Correlation matrix of industry-level characteristics

	EFD	TAN	SIZE	LIQ	DEP	DUR	EXP
EFD	1						
TAN	-0.113	1					
SIZE	0.043	0.272	1				
LIQ	-0.055	-0.688	-0.125	1			
DEP	0.335	-0.194	-0.178	-0.137	1		
DUR	0.441	-0.201	-0.062	0.200	0.361	1	
EXP	0.338	-0.369	-0.357	0.239	0.232	0.396	1

Note: EFD (external financial dependence), TAN (asset tangibility), SIZE (average firm size), LIQ (liquidity needs), DEP (capital depreciation), DUR (durability), EXP (export intensity).

B. Industry-level outcomes

We take the main dependent variable featuring in our analysis, industry-level growth outcomes, from the United Nations Industrial Development Organization (UNIDO) database. It covers 153 different countries—advanced, emerging, and developing—thus enabling us to broaden the scope relative to earlier analyses of the question at hand, which were limited to only 5 to 7 advanced economies (recall footnote 2).

We measure baseline industry growth by value-added growth, which is reported for 22 manufacturing industries at the two-digit INDSTAT2 2021, ISIC Revision 3.¹⁴ We use data reported in current local currencies and then deflate them using Consumer Price Indices taken from the Global Inflation Database (Ha, Kose, and Ohnsorge, 2021). We ensure that, for each industry, there are at least ten years of consecutive data, and the top and bottom one percent of the growth variables are winsorized to reduce the influence of extreme outliers.

¹⁴ While the original INDSTAT2 database includes 23 manufacturing industries, we exclude the “manufacture of recycling” industry due to insufficient observations.

To test the cost channel of monetary policy, we also create an industry price index, dividing value-added by the production index (as done by Samaniego and Sun (2015)). However, the sample size for the resulting price deflator is smaller by 30 percent because the coverage of the production index is smaller than that of value-added. To overcome this limitation, we also use the “EU KLEMS” and “World KLEMS” databases in separate exercises. The KLEMS databases have better quality observations on price deflators because they are taken directly from the National Accounts, not imputed from the production index (O’Mahony and Timmer, 2009). Another advantage of KLEMS is that it covers not only manufacturing but also service sectors (which are not included in UNIDO). However, these advantages come at some cost: the level of disaggregation of the manufacturing sector in KLEMS (12 sectors) is coarser than in UNIDO (23 sectors). Consequently, we regard these two datasets as complements, not substitutes.

Table A.1 in the online appendix provides a list of countries used in our analysis, including their industry and period coverage. The sample includes 102 countries (33 advanced economies and 69 emerging market and developing economies) for which proxies for monetary policy shocks are available with at least ten years of available industry-level data. Following the Rajan-Zingales tradition, the U.S. is not included in regressions to further alleviate reverse causality. Table A.2 reports the 22 manufacturing industries and their technological characteristics.

V. EMPIRICAL FINDINGS

A. Baseline results

Table 4 presents the main findings of this paper, resulting from the estimation of equation (1). Among the seven industry characteristics featured in our analysis, four (TAN, SIZE, DEP, and DUR) turn out to be statistically significant, while EFD, LIQ, and EXP are insignificant.

[Insert Table 4]

First, the positive estimate for the interaction terms on asset tangibility (TAN) and average firm size (SIZE), alongside the negative estimate on depreciation (DEP), lend support to the credit channel of monetary policy—suggesting that industries with greater difficulty to pledge collateral

are more sensitive to monetary policy. While this finding highlights the importance of credit as an amplification mechanism in the tradition of Kiyotaki and Moore (1997), it further points to the importance of unsecured financing in the monetary transmission mechanism, with there being a “flight to quality” (i.e., towards secured financing) in downturns; see Luk and Zheng (2022) for a recent model along these lines. Related to the difference in findings between Ottonello and Winberry (2020) and Jeenas (2019), as discussed in Cloyne et al. (forthcoming), our industry-level analysis (which does not suffer from the same endogeneity issues regarding firm-level financial constraints) can provide complementary evidence on the importance of the credit channel.¹⁵

Moreover, combined with the insignificant results on external financial dependence (EFD) and liquidity needs (LIQ), this suggests that the *ability* to draw external funds by pledging collateral is an important determinant of the output response, not dependence *per se* (which, our results suggest, does not expose firms excessively to changes in monetary policy provided they have access to collateral). While EFD and LIQ have been regarded as proxies for financial constraints (Kroszner, Laeven, and Klingebiel, 2007; Aghion et al., 2009), our findings indicate that they capture distinct aspects of financial frictions from the pledgeability of capital. Such orthogonality between EFD and TAN is also highlighted in Braun and Larrain (2005) and highlights the importance of distinguishing multiple dimensions of financial constraints.

Second, we find that industries producing durable goods (DUR) are more sensitive to changes in monetary policy. This is consistent with earlier findings in this literature, such as Dedola and Lippi (2005), Peersman and Smets (2005), and more recently Durante, Ferrando, and Vermeulen

¹⁵ Theoretically, it is unclear whether highly leveraged firms are financially constrained or not. Although they were typically treated as being constrained in earlier studies, high leverage also implies that these firms clearly did have access to external financing in the past (otherwise they would not end up as being highly leveraged). That is: there is an endogeneity issue here. Reflecting these contrasting views, Ottonello and Winberry (2020) and Jeenas (2019) find different relationships between corporate leverage and the investment sensitivity of U.S. firms to monetary policy: while the former finds lower sensitivity of high-levered firms, the latter finds them to be more sensitive to monetary shocks. Such contrasting findings are attributed to the empirical difficulty of identifying a shift in the marginal cost curve of investment (i.e., financial constraints) from a shift in the marginal benefit curve (i.e., investment opportunities); see Vats (2022). Our industry-level proxies for access to external financing do not suffer from this endogeneity issue at a business cycle frequency as they are constructed by taking the average (over decades) of U.S. firm-level variables belonging to each industry.

(2022). In line with these earlier studies, we view this as evidence supporting the interest rate channel of monetary policy.

Third, the insignificant coefficient on the interaction term with export intensity (EXP) suggests that industries more reliant on exports do not contract more following a monetary tightening; estimates continue to be insignificant when focusing solely on countries with floating currencies (using the classification from Ilzetzi, Reinhart, and Rogoff, 2019). This is consistent with models of “dominant currency pricing”, which predict that the exchange rate channel (if important) mostly runs through imports (Gopinath et al., 2020).

Having established these results, a natural follow-up question is: how large is the economic magnitude of the differential effects we estimated? Following the practice in the related literature (e.g., Rajan and Zingales, 1998; Aghion, Hemous, and Kharroubi, 2014; Lee, 2023), we calculate the difference in value-added growth changes for an industry whose industry characteristics move from the 25th percentile to the 75th percentile of the distribution when the country would face a one-standard deviation monetary policy shock.¹⁶ For statistically significant interaction terms (TAN, SIZE, DEP, and DUR), the differential effect ranges from 0.25 to 0.53 percentage points (see Table 4). Considering the average value-added growth of 2.49 percentage points in our sample, the differential effect accounts for a non-trivial share (up to 21 percent in the case of DEP), suggesting that our findings are also economically meaningful. To further gauge the relative importance of the technological characteristics, we report the results of a horserace, including every interaction term simultaneously, in the last column of Table 4. The coefficients on SIZE, DEP, and DUR remain statistically significant, suggesting that the credit channel and the interest rate channel can be seen as the most robust transmission channel, operating independently.

To test the cost channel, Table 5 presents the same set of results after replacing value-added growth with growth in the price deflator. Here, we do not find any evidence of price increases for

¹⁶ To be more specific, we multiply the point estimate of the parameter of interest (i.e., coefficient of the interaction term in the benchmark specification) by the standard deviation of the monetary policy shock and the interquartile range of each industry characteristic.

industries characterized by higher values for EFD or LIQ (both believed to proxy the importance of the cost channel).¹⁷

[Insert Table 5]

While our findings do not lend support to the empirical relevance of the cost channel of monetary policy, this null result might stem from the smaller sample size due to the narrower coverage of the production index or greater measurement error surrounding the industry price index imputed from UNIDO.¹⁸ To investigate this possibility, we have repeated the same exercise using the price deflator taken from KLEMS, which is less likely to be subject to measurement error (O’Mahony and Timmer, 2009). But, as shown in Table A.3 in the online appendix, we still do not find any support for the cost channel of monetary policy. The lack of evidence for the cost channel arising from our analysis is complementary to Rabanal (2007) and Henzel et al. (2009), who estimate a New Keynesian DSGE model embedding the working capital channel and find only a limited role for it.

B. Robustness checks

Our results suggest that industries producing durables and featuring assets that are more difficult to collateralize or characterized by a smaller size display greater sensitivity to monetary policy; here we document that these findings are largely robust to a battery of robustness checks.

Instrumental variable approach. Given the inherent difficulty of identifying a true monetary policy shock regardless of our proposed methods, the first robustness check moves away from treating $MPS_{c,t}$ as a structural shock in equation (1), instead considering it as a noisy proxy for a true monetary policy shock. Here, we proceed with a two-stage least squares (2SLS) approach. In the

¹⁷ Our conclusion about the relevance of each theoretical channel is robust to using weighted least squares (WLS), with weights given by the value added or the number of employees at the country-industry level, or the relative size of each industry within a country. This suggests that our findings are unlikely to be driven by observations without economic significance.

¹⁸ Unlike other industry outcomes directly taken from UNIDO, we imputed the price index from the ratio of the value-added to the production index, which might generate additional measurement error.

first step, we regress the interaction variable of changes in short-term policy rates and industry characteristics on the composite instrument (our shock proxy interacted with industry characteristics). In the second step, we re-estimate equation (1) using the exogenous variation driven by the instrument—that is, the fitted value of the first step. This IV approach helps alleviate remaining concerns arising from potential measurement errors in constructing the cross-country monetary policy shock series.

Table A.4 in the online appendix shows the IV estimation results. The Kleibergen-Paap F-statistics suggest that instruments are strong. The resulting second-stage estimates are close to the OLS coefficients in Table 4. If anything, statistical significance tends to increase, suggesting that our new proxy of monetary policy shocks is unlikely to suffer from a severe endogeneity bias when combined with multi-way fixed effects. The only meaningful change is that the export channel becomes statistically significant.

Short-term policy rate as a monetary policy instrument. Our empirical strategy assumes that the short-term policy rate is a good proxy for the monetary policy stance. While this is plausible for countries with a modern monetary policy framework (i.e., following a Taylor rule under inflation targeting), it may not hold for emerging or developing economies without a developed money market. Even for advanced economies, various central banks were targeting monetary aggregates in the past.

To guard against this possibility, we limit our analysis to the subsample of country-years that operated under an inflation-targeting framework (using the dating of Ha, Kose, and Ohnsorge, 2019). Our working assumption is that the adoption of inflation targeting indicates a transition toward a modern monetary policy framework, justifying our choice of the short-term policy rate as a measure of the monetary policy stance. Table A.5 presents the results, which confirm our baseline findings.¹⁹ Although the export channel becomes statistically significant at the 10% level, this channel again loses its significance in a horserace regression.

¹⁹ We also investigate whether the adoption of inflation targeting changes the empirical relevance of transmission channels. We do this by adding a triple interaction term ($X_i \times MPS_{c,t} \times IT_{c,t}$), where $IT_{c,t}$ is a dummy variable taking a value of one once country c adopted inflation targeting after year t . None of the triple interaction terms are statistically significant,

Placebo test. As we essentially use a difference-in-differences design, our identification hinges on the assumption that industries characterized by a certain value of X do not have different trends in growth than other industries before the change in monetary policy. While this “parallel trends” assumption is plausible (since monetary policy is normally not systematically conducted in response to industry-level developments), we examine this concern more directly via a placebo-type test. The placebo test using non-events is widely used in studies of the difference-in-differences type (e.g., Bertrand, Duflo, and Mullainathan, 2004; Duchin, Ozbas, and Sensoy, 2010).

As our baseline analysis deals with a continuous variable rather than a binary dummy, we instead change the timing of ΔMPS in equation (1) so that current industry growth is regressed on the future (not the past) value of monetary policy changes (i.e., the independent variable leading the dependent variable). To the extent that monetary tightening is not anticipated by industry growth differentials given controls, we should not find any statistically significant coefficients on the future independent variable other than by chance. Table A.6 confirms that essentially none of the interaction variables when using the lead of monetary policy shocks is statistically significant, suggesting that our “parallel trends” assumption is a reasonable one.

Country-specific industry characteristics. To test how reliable our key identifying assumption (i.e., stability of industry characteristics across countries) is, Table A.7 summarizes estimation results using alternative measures of average firm size in each industry: (i) a measure based on U.S. data only (as opposed to our baseline approach of working with the median across countries) and (ii) a country-specific measure. We then compare results with our baseline findings. We test both the credit channel (top panel) and the cost channel (bottom panel) of monetary policy.

Our previous conclusion about the (ir)relevance of both channels is maintained: while the credit channel continues to enjoy empirical support, the cost channel does not, which validates our identifying assumption that industry characteristics are stable across countries. Importantly, the size of coefficients using the country-specific measure is much larger than those using the U.S.-based

suggesting that the importance of the underlying monetary transmission channels has not been altered by the adoption of inflation targeting.

measure, consistent with the notion that measurement error (stemming from using the U.S. statistics as a noisy proxy for the rest of the world) induces an attenuation bias, working against finding any significant results.

C. Asymmetries in the transmission channels

State of the financial and business cycles. Earlier papers have presented evidence that the response of the economy to monetary policy shocks depends on the state of the economy (e.g., Tenreyro and Thwaites, 2016; Jordà, Schularick, and Taylor, 2020). As argued in Bernanke, Gertler, and Gilchrist (1996), the credit channel predicts that monetary policy has stronger effects when financial conditions are tight. Consequently, we can test the importance of this channel by analyzing whether the coefficient estimates on the industrial characteristics that we associate with the credit channel tend to be larger during bad times.

To test this hypothesis, we adopt the smooth transition approach proposed by Auerbach and Gorodnichenko (2012) and estimate the following regression:

$$Y_{i,c,t+1} = \alpha_{i,c} + \alpha_{i,t} + \alpha_{c,t} + \beta^E((1 - F(z_{c,t-1})) \times X_i \times MPS_{c,t}) + \beta^C(F(z_{c,t-1}) \times X_i \times MPS_{c,t}) + \gamma Share_{i,c,t} + \varepsilon_{i,c,t+1}, \quad (3)$$

$$\text{with } F(z_{c,t}) = \frac{\exp(\frac{\theta z_{c,t} - \mu_z}{\sigma_z})}{1 + \exp(\frac{\theta z_{c,t} - \mu_z}{\sigma_z})}, \quad \theta > 0.$$

Here, $z_{c,t}$ is an indicator of the state of the economy specific to each country (the state of the credit cycle), μ_z is a parameter that controls what proportion of the sample the economy spends in either state, σ_z is the standard deviation of the state variable z , and $F(z_{c,t})$ is the corresponding smooth transition function between the two states and enters the equation with a lag to mitigate reverse causality. The coefficients β^E and β^C capture the state-dependent effect of monetary policy during credit expansions and contractions, respectively. This approach considers a continuum of states to compute the impact, thereby making resulting estimates more precise.

The parameter $\theta > 0$ determines how smooth a transition is between the two states. As θ increases, the transition becomes more sudden: $\theta \rightarrow \infty$ corresponds to the binary case while setting

$\theta = 0$ is equivalent to the original linear specification of equation (1). Following Auerbach and Gorodnichenko (2012), we choose $\theta = 1.5$, but our results are largely invariant to θ . We choose the country-specific value of μ_z to make sure that each country evenly splits its time between expansions and contractions. This approach allows for a direct test of whether the monetary transmission channels vary over the credit cycle.

When it comes to implementation, we face the difficulty that, unlike for advanced economies, where credit price-based measures of financial conditions are available (for example, credit spreads or excess bond premiums emphasized in Gilchrist and Zakrajšek, 2012), these measures are difficult to construct in emerging or developing economies due to the lack of developed debt markets. Given this reality, we measure financial conditions by the so-called credit gap, defined as a cyclical deviation of the private credit to GDP ratio from its trend.²⁰ We proceed by using a *quantity*-based credit measure and isolate the cyclical component from its trend using the Hamilton filter (Hamilton, 2018) to account for financial deepening over time (i.e., private credit gap to distinguish between good and bad times). The results reported in Table 6 suggest that the interaction terms capturing the credit channel (TAN, SIZE, and DEP) tend to be larger in absolute value and/or associated with higher t-statistics during credit contractions, consistent with the financial accelerator mechanism.²¹

[Insert Table 6]

We further check whether the strength of the credit channel depends on the state of business cycle by replacing $z_{c,t}$ in Equation (3) with annual real GDP growth. The results reported in Table A.9 in the online appendix suggest that the strength of the various monetary transmission channels also varies with the state of the business cycle. Similar to the case of the credit cycle, the interaction terms proxying the credit channel (TAN, SIZE, and DEP) are larger during bad times, lending further support to the financial accelerator mechanism and consistent with the recent finding by

²⁰ This exercise uses “Domestic credit to private sector (% of GDP)” from the World Bank.

²¹ Table A.8 in the online appendix confirms that our findings are robust to using the one-sided HP filter.

Vats (2022) that financially-constrained firms respond more to monetary policy shocks during economic downturns.

Amplification of the credit channel of monetary policy. Our results so far strongly point to the empirical relevance of the credit channel of monetary policy. In this subsection, we jointly consider other states of the economy, which are known to affect the credit channel of monetary policy, to shed further light on this channel. The first potential candidate is the level of financial development. As originally discussed by Rajan and Zingales (1998), financial development tends to be of greater benefit to credit-constrained industries. Thus, one can expect that financial development would weaken the credit channel of monetary policy. Following Rajan and Zingales (1998), we use the ratio of private credit to GDP to measure financial development and add its interaction with X as an additional control to our regression (1), that is we estimate:

$$\begin{aligned}
 Y_{i,c,t+1} = & \alpha_{i,c} + \alpha_{i,t} + \alpha_{c,t} + \beta(X_i \times MPS_{c,t}) + \varphi(X_i \times U_{c,t}) \\
 & + \theta(X_i \times MPS_{c,t} \times U_{c,t}) + \gamma Share_{i,c,t} + \varepsilon_{i,c,t+1},
 \end{aligned} \tag{4}$$

with our measure of financial development taking the place of $U_{c,t}$ in equation (4).

The slow-moving nature of financial development differentiates this exercise from the one in equation (3) in which *cyclical* financial conditions specific to each country interact with monetary policy shocks. Before estimating equation (4), we estimate the version without the triple interaction term to check whether our measure of monetary policy shocks is truly orthogonal to potential confounding factors.²² Table A.10 in the online appendix confirms that the inclusion of financial development hardly changes the channel through which monetary policy shocks affect industry growth.²³ More importantly, Table A.11 shows that the triple interaction terms capturing the credit

²² Despite the use of arguably exogenous monetary shock estimates and our inclusion of multi-way fixed effects, we cannot fully exclude the possibility that other factors correlated with monetary policy shocks have heterogeneous effects on industry growth.

²³ Although many of the interaction terms on financial development are statistically insignificant, our results do not contradict the original findings in Rajan and Zingales (1998) because external financial dependence—the key interest of Rajan and Zingales (1998)—is highly statistically significant in our sample. While we exploit the annual variation in financial development in a given country, Rajan and Zingales (1998) and subsequent studies documenting an important

channel (TAN and DEP) are statistically significant, suggesting that the credit channel of monetary policy is stronger in less-developed financial markets.

A second possible confounding factor is severe crises (e.g., of the banking-, currency-, or sovereign debt-type) during which the central bank tends to employ aggressive policy actions and the external financing premium tends to rise.²⁴ To investigate whether the credit channel of monetary policy is amplified during crisis episodes, we employ an updated crisis database constructed by Laeven and Valencia (2020), which incorporates a comprehensive list of banking, currency, and sovereign debt crises. Consistent with the financial accelerator mechanism, the statistically significant interaction terms for SIZE and DEP in Table A.13 in the online appendix confirm that the credit channel of monetary policy is amplified during crisis episodes (when credit constraints are more likely to be binding).

VI. CONCLUSION

This paper analyzes how the effects of monetary policy vary with various industry characteristics. To do so, we have constructed a panel dataset collecting estimates of monetary policy shocks for a sample covering 176 countries—an effort that will hopefully be of use to other researchers.²⁵ Ultimately, our approach does not solely rely on traditional approaches to monetary policy shock identification but also combats the endogeneity problem through the inclusion of a simple-yet-powerful set of fixed effects. We achieved this by shifting focus away from analyzing the

role for financial development (e.g., Raddatz, 2006; Levchenko, Rancière, and Thoenig, 2009; Ilyina and Samaniego, 2011) exploit cross-country variation in financial development and focus on long-term growth instead.

²⁴ Moreover, severe crises might coincide with sudden changes in monetary policy and at the same time interact with industry characteristics when affecting industry growth. Kroszner, Laeven, and Klingebiel (2007), and Dell’Ariccia, Detragiache, and Rajan (2008), for example, find that industries with heavier external financial dependence suffer more from banking crises. When adding this crisis dummy for $U_{c,t}$ in (4) without the triple interaction term, Table A.12 in the appendix shows that monetary policy shocks bring about distinct effects from crises.

²⁵ For example, Guérin (2023) finds supporting evidence of the credit channel of monetary policy using our monetary policy shock estimates and cross-country firm-level data from Orbis.

overall effect of changes in the stance of monetary policy—analyzing the *differential* impact linked to industry-level characteristics instead.

One must be careful in interpreting our estimation results because the link between empirical proxies (i.e., industry characteristics) and theoretical channels is not perfect. Without fully-structural models, we cannot provide a definite answer to the importance of theoretical channels. Moreover, since our dependent variable is output (not investment), our inference is somewhat indirect—only looking at outcomes in terms of value-added growth in each industry (rather than looking at the response of investment, or other “intermediate” variables). Nevertheless, building on earlier studies linking the included industry characteristics to various monetary transmission channels, the statistical and economic significance of the differential effects is consistent with the credit channel and the interest rate channel of monetary policy playing a significant role.

The credit channel appears to be amplified during periods of tightened credit conditions or economic recessions as well as in countries with less developed financial markets. In contrast, we do not find evidence consistent with the cost channel of monetary policy, and only limited evidence for a channel running through exports. The latter finding aligns well with recent work on “dominant currency pricing” (Gopinath et al., 2020) which suggests that exchange rate movements have only minor effects on exports, with any exchange rate channel of monetary transmission mostly working through imports.

Zooming in on the credit channel, we find that the ability to secure external financing (i.e., having access to collateral) is more relevant to the transmission of monetary policy than the need for external financing. Our results suggest that firms with high external financing needs do not suffer more following monetary contractions, conditional on having access to collateral. This distinction between the “ability to secure” and “need for” external financing has not been made in earlier studies on the monetary transmission mechanism and may warrant further study to improve our understanding of it. For one, it points to the importance of cyclical fluctuations in *unsecured* debt, with there being a “flight to quality” out of unsecured (into secured) lending during economic slowdowns.

25	Rubber and plastics products	0.900	0.685	0.448	-0.628	1.105	-1.070	-0.569
26	Other non-metallic mineral products	-0.732	1.577	-0.132	-0.305	-0.228	0.892	-0.434
27	Basic metals	-0.758	1.009	-0.701	-0.124	-1.614	0.892	0.077
28	Fabricated metal products, except machinery and equipment	-0.262	-0.125	0.696	-0.104	-0.950	0.892	-0.638
29	Machinery and equipment n.e.c.	0.678	-0.836	-1.318	0.098	0.264	0.892	3.748
30	Office, accounting and computing machinery	1.618	-0.719	1.721	0.704	0.636	0.892	-0.281
31	Electrical machinery and apparatus n.e.c.	1.592	-0.719	-0.676	0.704	0.636	0.892	-0.281
32	Radio, television and communication equipment and apparatus	1.618	-0.719	0.466	0.704	0.636	0.892	-0.281
33	Medical, precision and optical instruments, watches and clocks	1.618	-0.962	-0.644	0.905	0.520	0.892	1.094
34	Motor vehicles, trailers and semi-trailers	0.052	-0.215	-0.908	0.300	1.435	0.892	0.924
35	Other transport equipment	0.052	-0.215	1.168	0.300	1.435	0.892	0.924
36	Furniture; manufacturing n.e.c.	0.078	-0.386	0.055	0.078	0.356	0.892	-0.116

Note: The indices for external financial dependence (EFD), asset tangibility (TAN), and depreciation (DEP) are taken from Samaniego and Sun (2015); average firm size (SIZE) is computed using the UNIDO database; the index for liquidity needs (LIQ) is taken from Raddatz (2006); the dummy for durability (DUR) is taken from Dedola and Lippi (2005); the index for export intensity is taken from Giovanni and Levchenko (2009). Each index is normalized to have a zero mean and unit standard deviation over all industries.

Table A.3. Robustness check: alternative KLEMS data

Dependent variable	(I) Value-added growth	(II) Price index growth
<i>EFD</i> × <i>MPS</i>	-0.179 (0.330)	0.285 (0.290)
Differential effect (in percentage points)	-0.504	0.803
R-squared	0.502	0.489
Observations	8155	7880

Note: The dependent variables are (i) the annual growth rate of real value-added for each industry-country pair and (ii) the annual growth rate of price index growth for each industry-country pair. Lacking proxies for every industry characteristic directly corresponding to the KLEMS industry specification, we can only use an alternative version of EFD for this exercise. We take external financial dependence from Tong and Wei (2021) at the SIC three-digit sector level, including both manufacturing and non-manufacturing sectors, and then aggregate it up to the two-digit level in which the recent KLEMS databases are available. We only report interaction coefficients for brevity. Estimates are based on equations (1) and (1') but using value-added and price data from KLEMS. Clustered standard errors at the country-time level are reported in parenthesis. *, **, *** denote significance at 10, 5, and 1 percent, respectively.

Table A.4. Robustness check: IV regression

Dependent variable: real value-added growth

Observations	42369	42369	42369	42369	42369	42369	42369

Note: The dependent variable is the annual growth rate of real value-added for each industry-country pair. Estimates are based on equation (4). Credit expansions and contractions are identified using the cyclical component of the private credit-to-GDP ratio. Clustered standard errors at the country-time level are reported in parenthesis. *, **, *** denote significance at 10, 5, and 1 percent, respectively.
